(Received 17 March 2006; revised manuscript received 19 April 2006; published 24 May 2006)

The ferromagnetic transition temperature \( T_C \) of a two-band double-exchange (DE) model for colossal magnetoresistance materials is studied using dynamical mean-field theory in wide ranges of coupling constants, hopping parameters, and carrier densities. The results are shown to be in good agreement with Monte Carlo simulations. When the bands overlap, the value of \( T_C \) is found to be much larger than in the one-band case, for all values of the chemical potential within the energy overlap interval. A nonzero off-diagonal hopping produces an additional boost of \( T_C \), showing the importance of these terms, as well as the concomitant use of multiband models, to increase the critical temperatures in DE-based theories.

Colossal magnetoresistance (CMR) rare-earth perovskites have attracted considerable attention due to their rich magnetic and structural phase transitions.\(^1\) The CMR effect, namely an extremely large drop in resistivity caused by a magnetic field, occurs at the transition between a low-temperature ferromagnetic (FM)-metallic ground state and a high-temperature paramagnetic-insulating phase, i.e., near transition temperature \((T_C)\). A basic aspect of CMR physics is that the mobile carriers (Mn-E\(_{g}\)-symmetry electrons) are strongly coupled ferromagnetically to localized spins (Mn \( t_{2g}\)-symmetry electrons). The electron motion influences the core spin’s alignment leading to ferromagnetism. The basic model used to describe CMR materials is the double-exchange (DE) model,\(^2\) formulated with one localized spin per site coupled to mobile carriers via a Hund’s coupling \(J\) much larger than the hopping amplitude \(t\) (Ref. 3). While DE ideas explain qualitatively the ferromagnetism, much of the CMR physics is still under debate.\(^4,5\) This is in part caused by the absence of fully reliable many-body techniques to study the complicated DE models applied to CMR compounds. Despite a considerable effort carried out within dynamical mean-field theory (DMFT) in the context of one-band models for CMR (Ref. 6), the realistic case of two active bands has received much less attention since its analysis is far more difficult. Only MC and static mean-field approximations have been applied to the realistic multiband problem,\(^3\) the DMFT treatment being notoriously absent.

In this paper the DMFT method is applied to the analysis of \( T_C \) of a two-band model for CMR materials. Its results are contrasted against Monte Carlo (MC) simulations and found to be in good agreement. Besides this nontrivial technically DMFT+MC contribution, we also unveil the key role of the off-diagonal hopping amplitudes to increase the critical FM temperature. This effect, which, to the best of our knowledge has not yet been discussed in literature, may lead to creative procedures to boost \( T_C \) in real materials. Our DMFT study is general, with two \( s=1/2 \) active bands, arbitrary couplings, hoppings, and carrier densities \( p \).

The DE Hamiltonian for the two-orbital model is

\[
\mathcal{H} = - \sum_{i,l',\alpha}(t_{l'\alpha}^{i} c_{l'\alpha}^{i\dagger} c_{l\alpha}^{i}) + H.c. - 2 \sum_{i,l} J_{l} S_{l} \cdot s_{l,i},
\]

where \( l, l' (=1,2) \) are the \( e_{g}\)-orbital indexes, \( i, j \) label the sites, \( c_{l\alpha}^{i} \) destroys an electron at site \( i \) in the orbital \( l, s_{l,i} = c_{l,\alpha}^{i \dagger} \sigma_{\alpha \beta}^{l} c_{l,\beta}^{i} \) is the electronic spin (\( \sigma^{l}=\text{Pauli vector} \)), \( \alpha \) and \( \beta \) are spin indexes, \( S_{l} \) is the spin of the local moment at site \( i \), assumed here classical (\( S_{l}=\pm S_{m} \)), where \( S_{m} \) is a randomly orientated unit vector, and \( J_{l} \) is the coupling between the core spin and the conduction electrons of orbital \( l \). While for \( l=l' \) we refer to \( t_{l} \) as the direct-orbital hopping (\( \equiv t_{l} \)), for \( l \neq l' \) the off-diagonal \( t_{l'l'} \) is referred to as the “interorbital” hopping (\( t_{l'l'} \)). The active orbital bands couple through the simultaneous scattering of carriers on the same core spin, as well as through the exchange of carriers via the off-diagonal hopping. While the first coupling clearly causes an increase in \( T_C \) when the bands overlap within the same energy interval, namely when \( J_{l} \) are closed, the electron exchange among bands is also shown to induce higher \( T_C \) even when the \( J_{l} \)’s are very different.

The inclusion of other terms, such as the antiferromagnetic exchange \( J_{AF} \) among core spins and/or the cooperative Jahn–Teller phonons, will need a sophisticated “cluster” DMFT where at least some short-distance effects are considered. For this reason, this study using the DMFT on a two-band model focuses on the simplest case where only the FM phase is relevant, the competition with other phases being left for future studies.

**DMFT results.** Within DMFT, the self-energy is momentum independent; \( \Sigma(\mathbf{p},i\omega_{n}) \rightarrow \Sigma(i\omega_{n}) \) \( \left[ \omega_{n}=(2n+1)\pi T \right. \) are the Matsubara frequencies]. Hence, the information about the hopping of carriers on and off lattice sites is carried by the bare Green’s function \( G_{0}(i\omega_{n}) \). Within one-band models, the local effective action \( S_{\text{eff}}(\mathbf{p}) \) defined by \( G_{0} \) is quadratic in the Grassman variables.\(^6,7\) Hence, the full Green’s function \( G \) can be solved by integration with the result: \( \langle G(i\omega_{n}) \rangle = \langle G_{0}(i\omega_{n}) + i\lambda_{\text{JW}}^{s} \rangle^{-1} \) (Refs. 6 and 8). If two orbital bands are active, then one rewriting the average above for each
band, \( \langle G_l(i\omega_n) = [G_{0l}^{-1}(i\omega_n) + J_S \rho \sigma]^{-1} \rangle \), and solve the equations for the coupled Green's functions, \( (G_{0l}^{-1}(i\omega_n) = z_n - i\theta_l'(G_{l}(i\omega_n) - i\theta_l'(G_{-l}(i\omega_n)) \ (l \neq l') \), on a Bethe lattice with a semicircular noninteracting density of states (DOS) \( \omega \) = \( \frac{\sqrt{4t'^2 - \omega^2}}{2\pi} \), where \( z_n = i\omega_n + \mu \) (\( \mu = \text{chemical potential} \). \( t' \) carries in \( G_{0l} \) the information about the second band \( l' \) through \( G_{l'} \). To find \( T_C \), we parametrize \( G_{0l}^{-1} \) as \( G_{0l}^{-1}(i\omega_n) = (z_n + \frac{1}{\omega_n}) \delta + Q_l(i\omega_n) \sigma_3 \), and linearize \( G_{0l}^{-1} \) with order parameter \( M \) (Ref. 8). Up to first order in \( M \),

\[
(G_{0l}^{-1}(i\omega_n) = z_n + R_l(i\omega_n), \]

a similar equation for \( R_l \) \((l' \neq l) \) can be obtained by interchanging the band indexes \( l \rightarrow l' \). Despite the extreme complexity of Eqs. (2), we managed to perform analytical calculations to decouple the equations set and to obtain separate equations for \( R_l \) \((l=1, 2) \). The polynomial coefficients of the ninth-order equations for \( R_l \) which are solved numerically, are combinations of all parameters of the model, i.e., couplings and hoppings (not reproduced because of their size). For \( t' = 0 \), the ninth-order equations reduce to the third-order ones: \( R_1^2 + 2z_n R_l^2 + (z_n^2 + t'^2) R_l + z_n R_l^2 = 0 \). At \( \mu = 0 \) and with the substitution \( i\omega_n \rightarrow \omega \), Eq. (2) gives the interacting electronic DOS at \( T = 0 \) (Ref. 9). If \( t' \neq 0 \), then, besides its own parameters \( t_l \) and \( J_l \), DOS \( t_l \) depends also on the parameters characterizing the other band \( l' \), i.e., \( t_{l'} \) and \( J_{l'} \), this interplay of parameters describing the coupling of bands. The obtained equation for \( Q_l(i\omega_n) \),

\[
Q_l = \frac{2}{3} J_{l'M} + Q_l \frac{2}{3} J_{l'M} + Q_{l'} \frac{2}{3} J_{l'M} + Q_{l'} \frac{2}{3} J_{l'M} + Q_{l'} \frac{2}{3} J_{l'M} = 1,
\]

leads us to an implicit expression for \( T_C \) in the form

\[
\sum_{j=1}^{2} \sum_{n=0}^{\infty} \frac{2 - 2t'^2J^2}{3(2J_l'^2 - J_l'^2)^2 - 3t'^2(B_l^2 - J_l'^2) - 2t'^2J_l^2} = 1,
\]

where above, if \( l = 1 \) (2), then \( l' = 2 \) (1). At \( t' = 0 \), Eq. (4) reduces to

\[
\sum_{j=1}^{2} \sum_{n=0}^{\infty} \frac{1 - 2t'^2J^2}{3(2J_l'^2 - J_l'^2)^2 - 3t'^2(B_l^2 - J_l'^2) - 2t'^2J_l^2} = 1,
\]

where \( B_l \) satisfies \( B_l^3 - z_n B_l^3 + (\frac{1}{\omega_n} - 2J_l^2)B_l + z_n J_l^2 = 0 \). We tested Eqs. (4) and (5) in several cases: (1) at \( t_1 = t_2 = 0 \) and \( J_2 = 0 \) we recovered the one-band model results reported in Ref. 10; (2) at \( t_2 = t_1 = 0, J_2 = 0, \) and \( J_1 \rightarrow \infty \), the results of Ref. 7 are reproduced. Details on the calculations above will be published elsewhere. From Eq. (4), the \( T_C \) contained in the Matsubara frequencies was extracted numerically. Equation (5) predicts an increase in \( T_C \) only for the values of \( \mu \) within the energy overlap interval.

In Fig. 1(a), the DOS of \( \omega \) at \( J_1 / t_1 = 25 \) and \( J_2 / t_2 = 15 \) is shown for several \( t_{l'} \). Our \( J_1 / t_1 \) are much larger than the value \( (J_1/t_1)_{\text{min}} = 1.4 \) that corresponds to the electron and hole bands formation, and the value \( J_1/t_1 = 8 \) captured in the one-band model large enough to capture properly the FM features of CMRs (Ref. 11). Thus, the electron bands are centered at \( \omega_1^* = 25 \) and \( \omega_2^* = 15 \) inside the electron-hole symmetry, are not shown here for simplicity. For clarity, we plotted DOS for \( \omega_1^* = 25 \) and \( \omega_2^* = 15 \) due to the electron-hole symmetry, are not shown here for simplicity. For clarity, we plotted DOS for \( \omega_1^* = 25 \) and \( \omega_2^* = 15 \).

In Fig. 2(a), the total interacting DOS of \( \omega \) (Ref. 9) at \( t_1 = 1, t_2 = 1/3 \rightarrow 0.33 \) is shown, for different \( t_{l'} \) in the case when the bands fully overlap \( J_1/J_2 = 1 \). The electron exchange effects not only increases the effective number of interacting electrons in each band, but also extends the energy region occupied by the bands. However, the total number of interacting electrons does not change, the bands being fully filled for \( p = 2 \). While at \( t_{l2} = 0 \) [Eq. (5)] the increase in \( T_C \) is due to the overlap of bands [short-dashed curve in Fig. 2(b)], when \( t_{l'1} = 0 \) [see Eq. (4)] the exchange effect further boosts \( T_C \) [Fig. 2(b)].
Monte Carlo results. The Hamiltonian (1) is also studied using the MC methods widely applied to Mn oxides in the limit \( J \to \infty \) (Ref. 11). Hence, the \( e_g \) spins are perfectly aligned with the \( t_{2g} \) spin. The technique involves finding the eigenvalues of the Hamiltonian matrix at each MC step corresponding to an updated set of localized spins. Although this substantially limits the size of the clusters being simulated, the results for small lattices are numerically exact and they allow for a direct comparison with DMFT. We simulate lattices of sizes \( 8^2 \) in two dimensions and \( 4^3 \) in three dimensions. The core spins are treated classically, while the treat-

ment of the fermionic sector is exact. In all simulations \( 2 \times 10^4 \) MC steps are used, the first \( 10^4 \) being discarded in order to account properly for the thermalization of the random starting configuration. In finite dimensions, the hopping carries a direction index “\( \ell \)” that is \( t_{\ell \ell'} \). In two dimensions (three dimensions), \( t_{\ell \ell'} = -3t_{\ell \ell'} \), \( t_{\ell \ell'} = \sqrt{3}t_{\ell \ell'} \), \( t_{\ell \ell'} = \sqrt{3}t_{\ell \ell'} \), \( t_{\ell \ell'} = t_{\ell \ell'} = t_{\ell \ell'} = 0, t_{\ell \ell'} = 4/3 \), in the \( x, y \) (and \( z \) directions, respectively). The indexes \( l \) and \( l' \) stand for the two active \( x^2-y^2 \) and \( 3z^2-r^2 \) orbitals. \( t_{l=1} \) sets the energy unit. To find \( T_C \) we investigate the long-range spin-spin correlations

\[
S(x) = \frac{1}{N} \sum_{\ell} \langle \tilde{S}_{l \ell} \cdot \tilde{S}_{l + \ell} \rangle = \frac{1}{N} \sum_{\ell} \frac{\text{Tr}(\tilde{S}_{l \ell} \tilde{S}_{l + \ell} e^{-\beta t_{\ell \ell'}})}{\text{Tr}(e^{-\beta t_{\ell \ell'}})}
\]

where \( N \) is the total number of sites, \( T_C \) is the temperature for which \( S \to 0 \) upon heating, at the maximum allowed distance \( x_{\text{max}} \) in the clusters considered.

In Fig. 3, the results in two and three dimensions are displayed side by side for comparison. Error bars are less than the symbol size unless otherwise indicated. In panel (a), the spin-spin correlations at \( x_{\text{max}} \) for the same lattice used in (a). The one-band results are also shown (1b). The solid curve shows the \( T_C \) obtained from (a). (d-f) Same as in (a-c), but using a three-dimensional (3D) lattice of size \( 4^3 \). In all frames \( J_1 = J_2 \to \infty \).

FIG. 1. (Color online) (a) DMFT zero-temperature interacting DOS for \( J_1 = 25 \) and \( J_2 = 15 \) at different \( t_{l2} \). (b) \( T_C \) vs \( p \) for the cases shown in (a). Since the Hund’s couplings are very different, the bands and critical temperatures retain the semicircular form. (c) Zero-temperature interacting DOS for \( t_{l2} = 0.5 \), for the couplings indicated. (d) \( T_C \) vs \( p \) for the cases shown in (c). Even if the overlap of bands is narrow, the exchange of electrons is strong enough to induce a robust \( T_C \) at \( p = 1 \) (solid curve). In all frames \( t_1 = t_2 = 1 \).

FIG. 2. (Color online) (a) DMFT zero-temperature total interacting DOS for different values of \( t_{l2} \). (b) \( T_C \) vs \( p \) for the parameters indicated in (a). The solid curve corresponds to the realistic set of hoppings (e.g., LaMnO\(_3\)). In all frames \( t_1 = 1, J_1 = J_2 = 15 \). The one-band results are also shown (1b).

FIG. 3. (Color online) (a) MC spin-spin correlations at \( x_{\text{max}} = 4\sqrt{2} \) vs temperature for different \( p \), at \( t_1 = 1 \), \( t_2 = 1/3 \), and the \( t_{l2} \) indicated, using an \( 8^2 \) lattice. (b) Same as in (a), but changing \( t_{l2} \). (c) \( T_C \) vs \( p \) at different \( t_{l2} \) for the same lattice used in (a). The one-band results are also shown (1b). The solid curve shows the \( T_C \) obtained from (a). (d-f) Same as in (a-c), but using a three-dimensional (3D) lattice of size \( 4^3 \). In all frames \( J_1 = J_2 \to \infty \).
4^3 lattice. Moreover, we investigate $T_C$ versus $p$ at $t_1 = 1$, $t_2 = 1/3$, and different $t_{12}$. The results are in Fig. 3(b) for two dimensions and in Fig. 3(e) for three dimensions. The $T_C$ is maximum at $p=1$ and vanishes in the limits $p 	o 0$ and $p = 2$, with an overall semicircular form in the phase diagram, as seen in frames (c) and (f). The one-band phase diagram (denoted 1b) is also shown. Hence, as seen in (c) and (f), $t_{12}$ has a substantial effect in raising the $T_C$, which is in qualitative, and even in quantitative, agreement with DMFT. As $t_{12}$ increases from 0 to 1, the increase in $T_C$ can be as high as 100% in two dimensions and 60% in three dimensions.

The finite-size effects are checked using different boundary conditions and simulating clusters of up to $12^2$ in two dimensions and $5^3$ in three dimensions. In Fig. 4 the spin-spin correlations at $x_{\text{max}}$ (a) and the magnetization $|M|$ vs $T$ curves (b) are shown. The size effects are small, showing that our MC method detects the $T_C$ accurately.

**Conclusion.** We carried out a study of a multiband DE model applied to CMR using a powerful combination of DMFT and MC techniques. When two active bands are considered, the $T_C$ is maximized at $p=1$. DMFT shows that the interorbital hopping leads to an increase in $T_C$ at all $p$’s, even if the electron bands do not occupy the same energy interval. This is due to the electron exchange between the bands, which increases the effective number of interacting electrons within each band. Both DMFT and MC indicate that, if the bands fully overlap, besides the increase of $T_C$ due to the energy overlap, a further boost occurs when the interorbital hopping is turned on. The ideas developed here can be used to search for multiorbital FM materials with even higher $T_C$ than currently known, once the off-diagonal hopping is tuned up. Our study can be extended to diluted magnetic semiconductors, with similar results expected.$^{15}$

3. At large $J$ ($>1.4\hbar$) the $T_C$ vs $J$ is almost flat (Ref. 6).
8. The average $\langle X(m) \rangle = \int d\Omega_m X(m) P(m)$ is over the orientations $m$ of the local moment on site 0. $P(m) \propto \text{Tr} \left[ \exp \left( -S_{\text{eff}}(m) \right) \right]$ is the probability for the local moment to point in the $m$ direction (one-site probability) and can be obtained by integrating $\exp \left[ -S_{\text{eff}}(m) \right]$ over the Grassman variables. While $P(m)$ = $1/4\pi$ above $T_C$ (Ref. 7), in the FM phase near $T_C$, $P(m) \propto \exp(-\beta T_C M_m)$ (Ref. 10), where $\beta = 1/T$ and $M = \langle m \rangle_m$ is the local-moment order parameter, nonzero only below $T_C$.
9. $\text{DOS}(\omega) = -2 \text{ Im} \langle R(\omega) \rangle / \pi$, $\text{DOS}(\omega) = \Sigma \text{DOS}(\omega)$.
13. Concerns may arise about a two-dimensional (2D) lattice with a finite $T_C$, but our MC-simulated 2D system is expected to capture the physics of a real finite 3D system with a nonzero, but very small, coupling in the $z$ direction. This is due to the rapid growth of the correlation length of the 2D system upon cooling (Ref. 11).
14. With a bandwidth $W=1\text{ eV}$ at $p=1$, DMFT ($W=4\text{t}$), at $I_1 = I_2 = 15$, $t_1 = 0.25\text{ eV}$, $t_2 = t_1/3 \equiv 0.083\text{ eV}$. $t_1 = t_1^*(3) \equiv 0.144\text{ eV}$, gives $T_C \approx 370\text{ K}$, while MC gives in two dimensions ($W=6\text{t}$) at $t_1 \approx 0.17\text{ eV}$ the $T_C \approx 425\text{ K}$, and in three dimensions ($W=12\text{t}$) at $t_1 \approx 0.084\text{ eV}$ the $T_C \approx 407\text{ K}$.
