(Received 22 August 2011; published 21 October 2011)

Motivated by the recent discovery of Fe-based superconductors close to an antiferromagnetic insulator in the experimental phase diagram, here the five-orbital Hubbard model (without lattice distortions) is studied using the real-space Hartree-Fock approximation, employing a 10×10 Fe cluster with Fe vacancies in a $\sqrt{5} \times \sqrt{5}$ pattern. Varying the Hubbard and Hund couplings, and at electronic density $n = 6.0$, the phase diagram contains an insulating state with the same spin pattern as observed experimentally, involving 2×2 ferromagnetic plaquettes coupled with one another antiferromagnetically. The presence of local ferromagnetic tendencies is in qualitative agreement with Lanczos results for the three-orbital model also reported here. The magnetic moment $\sim 3\mu_B/\text{Fe}$ is in good agreement with experiments. Several other phases are also stabilized in the phase diagram, in agreement with recent calculations using phenomenological models.

Introduction. Among the most recent exciting developments in the field of Fe-based superconductors¹ is the discovery of superconductivity (SC) with $T_c \sim 30$ K in the heavily electron-doped 122 iron chalcogenide $\text{K}_{0.8}\text{Fe}_{2-x}\text{Se}_2$ and $(\text{Tl,K})\text{Fe}_{2-x}\text{Se}_2$ compounds.² These materials contain ordered Fe vacancies in the FeSe layers, increasing the complexity of these systems. Recent neutron-scattering results for the parent compound $\text{K}_{0.8}\text{Fe}_{1.6}\text{Se}_2$,³ with the Fe vacancies arranged in a $\sqrt{5} \times \sqrt{5}$ pattern, revealed an unexpected magnetic and insulating state involving 2×2 Fe plaquettes that have their four Fe spins ferromagnetically ordered, and with these plaquettes coupled to each other antiferromagnetically.⁴ The ordered magnetic moment is $3.31\mu_B/\text{Fe}$, the largest among all Fe pnictide and chalcogenide superconductors, and the magnetic transition occurs at a high temperature $T_N \approx 559$ K. Angle-resolved photoemission experiments for $(\text{Tl,K})\text{Fe}_{1.78}\text{Se}_2$ have revealed a Fermi surface (FS) with only electronlike pockets at the $(\pi, 0)$ and $(0, \pi)$ points and a nodeless superconducting gap at those pockets.⁵ The superconducting phase in these compounds cannot be explained by the nesting between hole and electron pockets.^{5,6} Moreover, the resistivity of these materials displays a behavior corresponding to an insulator in a robust range of the Fe concentration x ,⁷ suggesting that SC may arise from the doping of a Mott insulator, as in the cuprates. All these results certainly have challenged prevailing ideas for the origin of SC in these materials that were originally based on a nested FS picture and a metallic parent state.

Several theoretical efforts have recently addressed the exotic magnetic state that appears in the presence of vacancies. Band-structure calculations described this state as an antiferromagnetic insulator with a gap $\sim 0.4\text{--}0.6$ eV.^{8,9} Several model Hamiltonian calculations have also been presented and, in particular, two recent publications are important to compare our results against. Yu *et al.*¹⁰ analyzed this problem using a phenomenological $J_1\text{--}J_2$ spin model (see also Ref. 8) with nearest-neighbor (NN) and next-NN term superexchange couplings, studied via the classical Monte Carlo method. In this

analysis the couplings inside the 2×2 plaquettes and those between plaquettes were allowed to be different, and also to take positive or negative values. Five antiferromagnetic phases, including the phase found experimentally³ in $\text{K}_{0.8}\text{Fe}_{1.6}\text{Se}_2$, which was dubbed “AF1,” were found varying the J_1 and J_2 couplings.¹¹ From a different perspective that relies on a two-orbital (d_{xz} and d_{yz}) spin-fermion model for pnictides, and with tetramer lattice distortion incorporated, Yin *et al.*¹² studied the regime of electronic density $n = 1$ (one electron per Fe), where they also reported the presence of an AF1 state, found competing with a “C”-type state with wave vector $(\pi, 0)$.

In the present Rapid Communication, a more fundamental five-orbital Hubbard model, without lattice distortions, is investigated. Our main result is that increasing the Hubbard coupling U and the Hund coupling J , a robust region of stability of the AF1 state is found. Our effort allows to display the regions of dominance of the many competing states in terms of U and J/U , facilitating a discussion on possible phase transitions among these states by varying experimental parameters. A sketch of the AF1 state and its two main competitors, the C and AF4 states, is shown in Fig. 1. Our results agree qualitatively in several respects with the phenomenological studies of Refs. 10 and 12, particularly if a combination of the results of these investigations is made. Finally, also note that a recent study¹³ of the three-orbital Hubbard model¹⁴ using mean-field techniques¹⁵ has also reported the existence of an AF1 state but with orbital order (OO). The relation with our results will also be discussed below.

Models and methods. In this Rapid Communication, the standard multiorbital Hubbard model will be used. This model has been extensively described in several previous publications, by our group and others. More specifically, the model used is the five-orbital Hubbard model defined in Ref. 15 with the hopping amplitudes introduced in Ref. 16. By construction, this model has a FS that is in close agreement with band-structure results for the pnictides without vacancies.

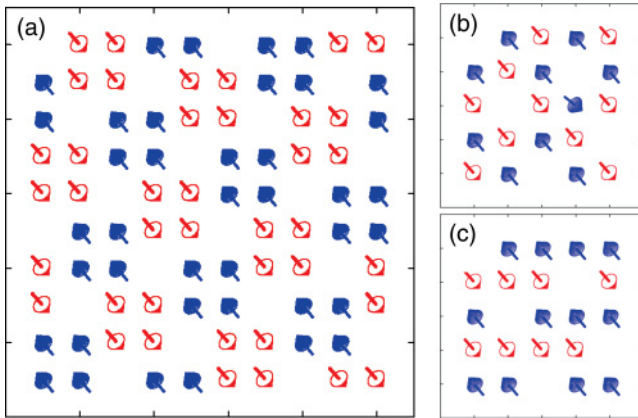

FIG. 1. (Color online) (a) Sketch of the AF1 state found to be stable in a region of the U - J/U phase diagram (see Fig. 2) in our HF approximation to the five-orbital Hubbard model, in agreement with neutron diffraction (Ref. 3). (b) A competing state dubbed AF4 (stable at smaller J/U 's in Fig. 2). (c) The C competing state. For (b) and (c), a subset of the 10×10 cluster used is shown.

The presence of the realistic AF1 state in our results, shown below, suggests that the same set of hoppings can be used in a system with Fe vacancies. The electronic density will be $n = 6.0$ (6 electrons/Fe) for all our five-orbital model results. The couplings are the on-site intraorbital Hubbard repulsion U and the on-site Hund coupling J . The on-site interorbital repulsion U' satisfies $U' = U - 2J$. The computational method employed for this five-orbital model relies on the study of a 10×10 cluster, sketched in Fig. 1(a), using periodic boundary conditions. In this cluster, several vacancies and 2×2 building blocks fit comfortably inside, giving us confidence that the magnetic order tendencies may not be dramatically affected by size effects.

With regard to the actual many-body technique used, here the real-space Hartree-Fock (HF) approximation was employed. The method is a straightforward generalization of that used recently in Ref. 17 in the study of charge stripe tendencies for the two-orbital model. This HF real-space approach was preferred over a momentum-space procedure to allow for the system to select spontaneously the state that minimizes the HF energy, at least for the finite cluster employed here. In practice, the many fermionic expectation values that appear in the HF formalism must be found iteratively by energy minimization. At the beginning of the iterative process, both random initial conditions as well as initial ordered states favoring the many phases that are anticipated to be in competition were employed. After each of the computer runs using different initial conditions have reached convergence, at a fixed U and J/U , a mere comparison of energies allowed us to find the ground state for those particular couplings. In our setup, typical running times for one set of couplings U - J/U required ~ 20 h of CPU time to reach convergence.¹⁸ Dozens of computer cluster nodes have been used to complete our analysis in a parallel manner.

Results. Our main results are summarized in the phase diagram shown in Fig. 2. Since the hopping parameters of Ref. 16 are already in eV units, our Hubbard coupling U is also displayed in the same units. The notation for

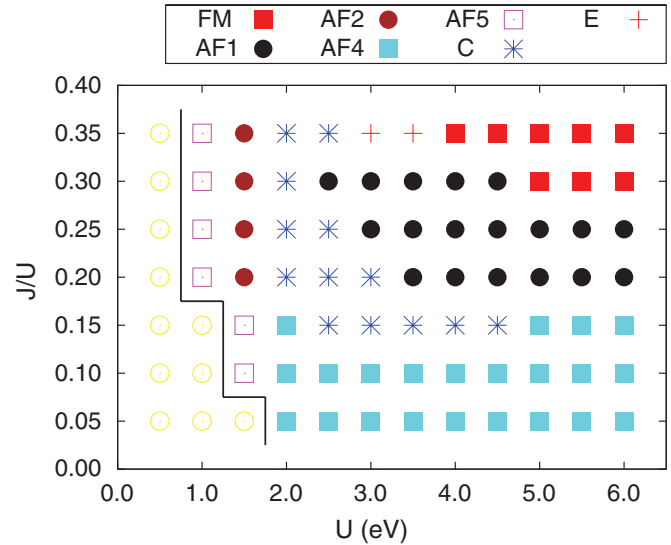

FIG. 2. (Color online) Phase diagram of the five-orbital Hubbard model with $\sqrt{5} \times \sqrt{5}$ Fe vacancies studied via the real-space HF approximation to a 10×10 cluster, employing the procedure for convergence described in the text. With increasing U , clear tendencies toward magnetic states are developed. The realistic AF1 state found in neutron-scattering experiments (Ref. 3) appears here above $J/U = 0.15$ and for U larger than 2.5 eV. The notation for the most important states is explained in Fig. 1 and for the rest in Refs. 8, 10, and 12. The region with low-intensity yellow (open) circles at small U is nonmagnetic (Ref. 19).

the many competing phases is that of Refs. 8, 10, and 12 to facilitate comparisons. The main result of the present Rapid Communication is that our phase diagram displays a robust region where the magnetic order unveiled by neutron diffraction³ [see Fig. 1(a)] is found to be stable. The ratio J/U needed for the AF1 phase to be the ground state is in good agreement with previous estimations for the same model, although obtained in the absence of vacancies, based on the comparison of the Hubbard model results against neutron and photoemission data.¹⁵ The ratio J/U is surprisingly similar between the pnictides and the chalcogenides. With regard to the actual value of U in eV's, the range unveiled in previous investigations that focused on the "1111" and "122" families of pnictides was ~ 1.5 eV (see Fig. 13 of Ref. 15). The increase to 2.5 eV in the present investigation is not surprising in view of the more insulating characteristics of materials such as $\text{K}_{0.8}\text{Fe}_{1.6}\text{Se}_2$, and suggests that merely adding vacancies to the intermediate U state of the pnictides (without vacancies) may not be sufficient to stabilize the AF1 state but an increase in U is also needed. Finally, with regard to OO, none is observed in the AF1 state in the range of U shown in Fig. 2, i.e., for $U \leq 6$ eV. In this range, the electronic density of all the orbitals (d_{xz} and d_{yz} in particular) is independent of the site location in the cluster analyzed. However, upon further increasing U to 8 eV and beyond, the *same* OO pattern found in the three-orbital model¹³ appears in our calculations (not shown explicitly), with the populations of the d_{xz} and d_{yz} orbitals now being different at all sites. It seems that with five orbitals the AF1 state manifests itself both with and without OO, depending on

FIG. 3. (Color online) Density of states of the AF1 and C phases sketched in Figs. 1(a) and 1(c), at the U 's indicated, $J/U = 0.25$, and using a 10×10 cluster. The gap at the chemical potential suggests that the AF1 state ($U = 3$ and 5) is an insulator, although with a mild U dependence in the value of this gap. On the other hand, the C state appears to have only a pseudogap at the Fermi level (Ref. 20).

U , while for three orbitals the intermediate phase with AF1 magnetic order and without OO is not present.¹³

Together with the realistic AF1 phase, Fig. 2 reveals several other states, and two of them are prominent. Keeping J/U constant but reducing U , the previously described C-type state [Fig. 1(c)] was found to be stable. This is reasonable since without Fe vacancies this state is the dominant spin order in the metallic and magnetic intermediate range of couplings.¹⁵ In $K_{0.8}Fe_{1.6}Se_2$, as the bandwidth is increased by, e.g., increasing the pressure, a transition from the AF1 to the C state could be experimentally observed. In these regards, our conclusions agree with Ref. 12 that the C state is the main competitor of the AF1 state. However, note that other states reported in Ref. 10 are also present in our phase diagram. For instance, the AF4 state [Fig. 2(b)] is stable in a large region of parameter space at small values of J/U . Thus, overall, our results support a combination of the main conclusions of Refs. 10 and 12.

The density of states (DOS) for the AF1 phase is shown in Fig. 3 for representative couplings. The presence of a gap at the chemical potential indicates an insulating state, in agreement with experiments.³ This is not surprising considering that the transport of charge from each 2×2 building block to a NN block may be suppressed due to the effective antiferromagnetic coupling between blocks, at least at large U and J . In other words, using a tilted square lattice made out of 2×2 superspin blocks, the state is actually a staggered antiferromagnet that is known to have low conductance. On the other hand, it is interesting to observe that the AF1 gap is only weakly dependent on U , suggesting that not only the increase in U is responsible for the insulating behavior but there must be other geometrical reasons that may contribute to the gap through quantum interference. This is reminiscent of results reported years ago for the insulating CE phase of half-doped manganites, a state that is stabilized in the phase diagram even in the absence of electron-phonon coupling due to the peculiar geometry of the zigzag chains involved in the CE state and the multiorbital nature of the problem, that

induces a band-insulating behavior.²¹ Thus, in agreement with recent independent observations,¹² our results suggest that the insulator stabilized in the presence of Fe vacancies may have a dual Mott and band-insulating character. Note also that the competing C state only has a pseudogap (Fig. 3), and thus it may be a bad metal.²⁰

With regard to the strength of the ferromagnetic (FM) tendencies in each of the 2×2 building blocks of the AF1 state, examples of the values of the magnetic moment m (in Bohr magnetons, assuming $g = 2$, and at $J/U = 0.25$) are $m = 3.87$ ($U = 3.0$), $m = 3.93$ ($U = 4.0$), and $m = 3.95$ ($U = 5.0$), in good agreement with neutron-diffraction results³ $m = 3.3$. Thus, the Fe spins in the AF1 superblocks are near the saturation value $4.0\mu_B$ at $n = 6.0$. Note that the competing C phase also has a surprisingly large moment $m = 3.5$ at $U = 2.0$ and $J/U = 0.25$.

Results for the three-orbital Hubbard model. The results reported thus far have been obtained under the HF approximation. To the best of our knowledge, better unbiased approximations for this model are not currently available. However, at least consistency checks of the present results can be carried out using the Lanczos technique restricted to the 2×2 cluster of irons that forms the AF1 state. For our problem, an additional simplification from five to three orbitals (d_{xz} , d_{yz} , and d_{xy}) is needed to reduce the Hilbert space to a reasonable size, thus here the model introduced by Daghofer *et al.*¹⁴ was used. The present Lanczos study is equivalent to a 12-site one-orbital Hubbard model which can be done comfortably with present-day computers even with the open-boundary conditions (OBC) employed here.²² Our focus has been on the total spin quantum number to search for FM tendencies in the 2×2 cluster. The main results are shown in Fig. 4 for the

FIG. 4. (Color online) Total spin of a 2×2 cluster using the three-orbital Hubbard model (Ref. 14) and the Lanczos technique, varying U and J/U . (a) is for ten electrons, while (b) is for 14 electrons. The “undoped” limit is for 16 electrons in the three-orbital model (Ref. 14). The figure shows that in these hole-doped clusters FM tendencies develop as U grows, at realistic J/U 's, compatible with the five-orbital HF results.

case of hole doping. These results indicate that with increasing U and J/U , FM tendencies indeed develop, in agreement with the five-orbital HF results (Fig. 2). With electron doping also FM tendencies were found (not shown). In these Lanczos results the transition from low to high spin is rather abrupt. However, in just one 2×2 cluster there is obviously no room to distinguish a fully FM state from an AF1 state, thus the large-spin region of the 2×2 cluster may correspond to any of the two if larger clusters could be studied. Nevertheless, solving exactly this case, it is confirmed that with increasing U (at realistic J/U 's), there is a clear tendency in the multiorbital Hubbard model toward local FM order in 2×2 clusters.

Summary. Real-space HF-approximation results for the five-orbital Hubbard model, supplemented by Lanczos calculations for three orbitals on a 2×2 plaquette, have been presented for a $\sqrt{5} \times \sqrt{5}$ arrangement of Fe vacancies. The phase diagram varying U and J/U contains the magnetic state found in neutron experiments.³ This state arises at intermediate U and J/U , and in the phase diagram it is not in contact with the paramagnetic metallic state of the weak-coupling limit. Thus, FS nesting cannot explain the stability of the AF1 magnetic state in the presence of Fe vacancies.¹² The

density of states shows that the AF1 state is an insulator, but since the gap does not present a strong dependence on U , its origin may reside in a combination of Hubbard and band-insulator features. As in recent spin¹⁰ and spin-fermion¹² model calculations, several other magnetic phases were found here, suggesting that transitions among these competing states, or among AF1 with and without OO,¹³ could be observed experimentally, particularly by modifications in the carrier's bandwidth.²³ Additional studies with more sophisticated tight-binding terms²⁴ will be performed to investigate if the results obtained here are model dependent, and to understand the effects of the magnetism on the possible symmetries of the pairing state.
